PJM Model Accuracy and Forecast Stability

This memo provides analysis of forecast results provided by PJM to Itron. PJM generated a series of estimated models and forecasts based on data that would have been available at five points in time. The timing of the forecasts is summarized as follows:

- Final2007 – Models are estimated using data through Oct 31, 2006. Forecasts are based on June 2006 economics (history and forecast).
- Final2008 – Models are estimated using data through Aug 31, 2007. Forecasts are based on September 2007 economics (history and forecast).
- Final2009 – Models are estimated using data through Aug 31, 2008. Forecasts are based on Dec 2008 economics (history and forecast).
- Final2010 – Models are estimated using data through Aug 31, 2009. Forecasts are based on Nov 2009 economics (history and forecast)
- Final2011 – Models are estimated using data through Aug 31, 2010. Forecasts are based on Dec 2010 economics (history and forecast)

All forecasts are based on economic data from Moody's. To generate the results it was necessary to gather the Moody's historical and forecast data values in place at each point in time for all of the economic factors used in construction of the Index variables. These factors are: Population, Households, Real Personal Income, Non Manufacturing Employment, Real Gross Metropolitan Product and Real Gross Domestic Product.

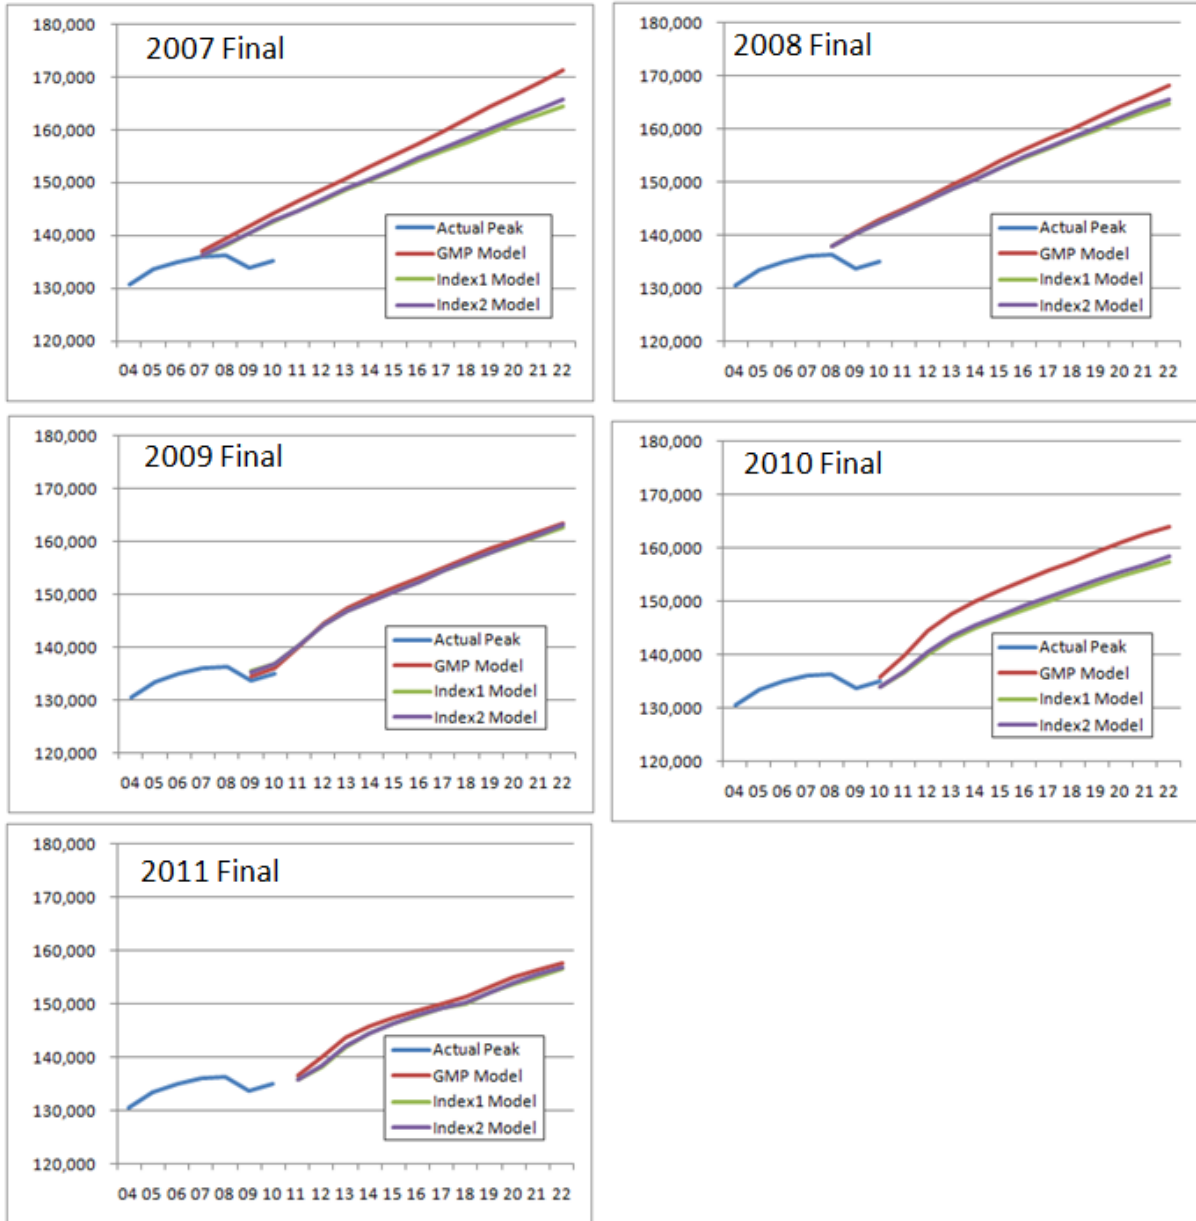

For each forecast vintage, three sets of models were estimated and used to generate daily coincident and non-coincident peak forecasts. The first model uses the standard PJM specification, based on GMP as the single driver. The second model uses the Index1 approach, which uses common weighting factors for all zones. The third model uses the Index2 approach, which uses different weightings based on revenue class sales for each zone.

Results for the annual summer peaks were provided for the PJM zones as well as the RTO total values. The annual peak forecasts at the RTO level are summarized in Figure 1. In this figure, each graph represents one forecast vintage. Each graph shows the three sets of forecast methods and also the actual weather normalized peak values through 2010.

Visual inspection of the forecasts shows the following:

- In the first forecast (Final2007), the GMP approach generated a higher overall forecast than the Index approaches. The difference was about 1,000 MW one year out, increasing to 5,000 MW in the later years.
- In the second forecast (Final2008), the differences narrowed. All approaches gave a very similar short-term forecast. The GMP approach again gave a higher forecast in the later years, but the difference fell to about 3,000 MW.

Figure 1: Forecasts of PJM Summer Peak

- In the third set of forecasts, the Index model accelerated slightly while the GMP method forecasts dropped to give similar short-term forecasts.
- In the fourth set of forecasts, the Index model accelerated slightly while the GMP method forecasts dropped significantly. The resulting gap is about 1,000 MW in the long term.
- In the most recent set of forecasts, the Index model forecasts remained relatively flat while the GMP method forecasts declined significantly. The resulting gap is about 1,000 MW of the index-based forecasts.

These results are used to calculate the accuracy of each forecast approach as well as to assess the bias of each approach.

Forecast Accuracy

To judge forecast accuracy, the total power per normalized actual peak values for 2008 are shown in Figure 2. This figure shows the accuracy statistics (1, 2, and 3-year errors).

Comparable statistics are provided for the Index and x2 method in Figure 4.

Figure 2: Accuracy Statistics for PJM Peak using GMP Method

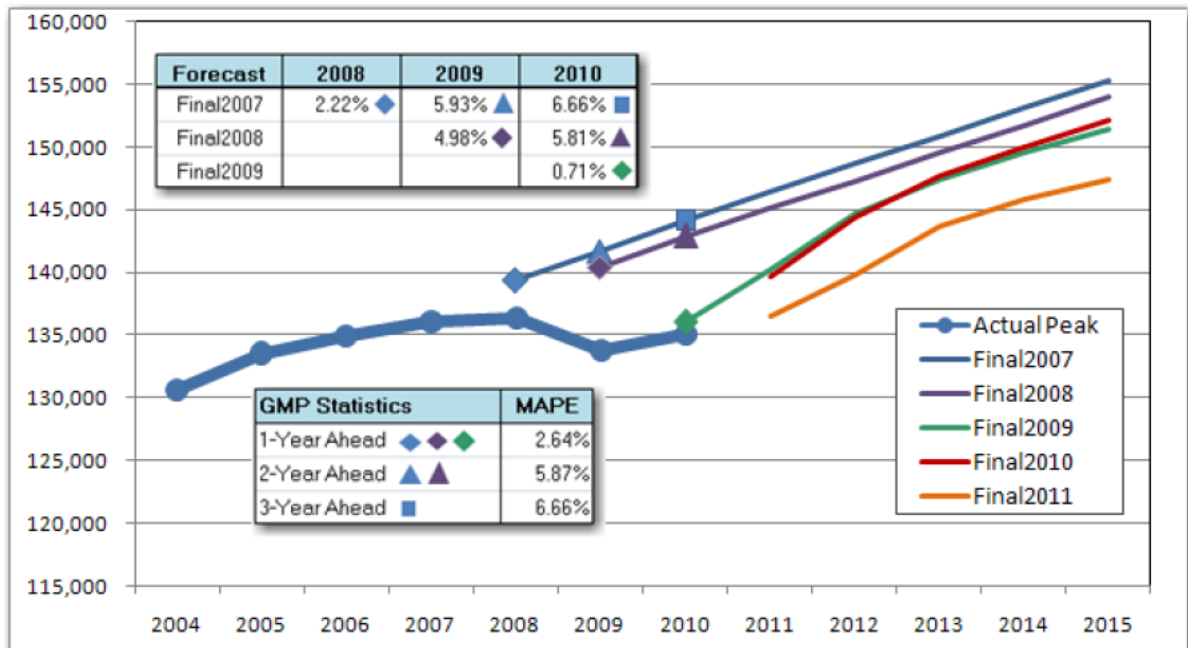

Figure 3: Accuracy Statistics for PJM Peak using Index1 Method

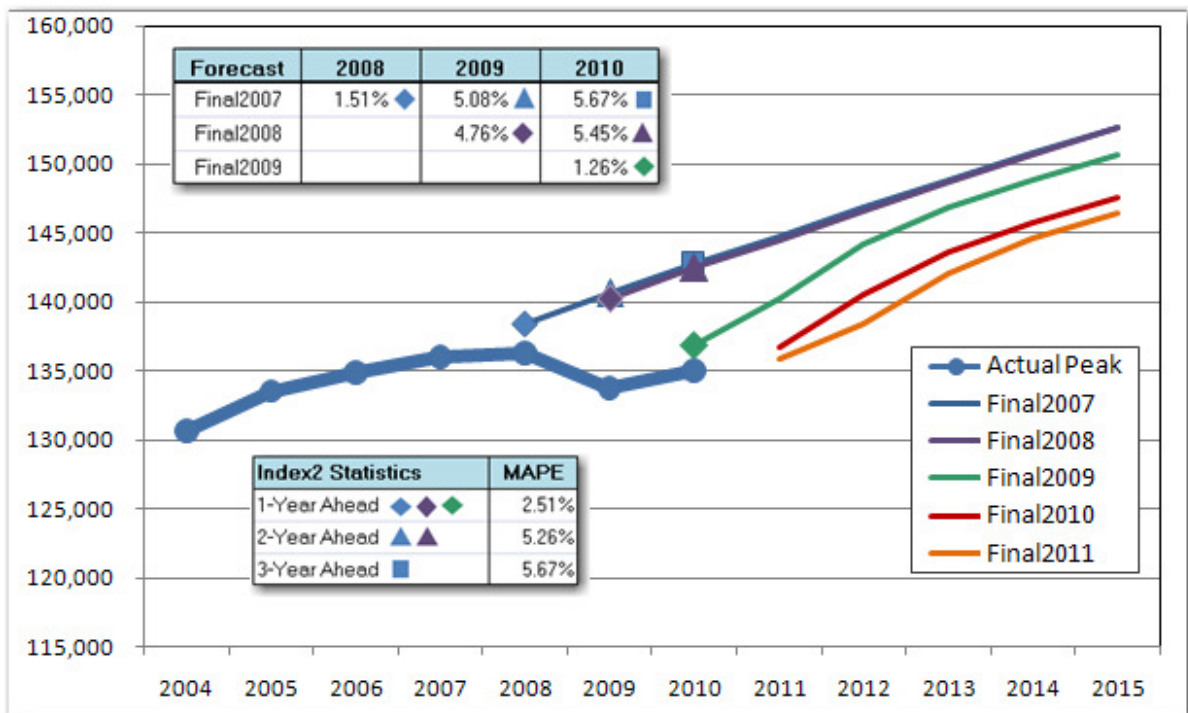

Figure 4: Accuracy Statistics for PJM Peak using Index2 Method

To compute 1-year ahead errors, three forecast values are used: the Final2007 forecast for 2008, the Final2008 forecast for 2009, and the Final2009 forecast for 2010. These

forecasts are represented by diamond shape symbols on each forecast line. To compute 2-year ahead errors, two forecast values are used: the Final2007 forecast for 2009 and the Final2008 forecast for 2010. These forecasts are represented by triangular symbols on each forecast line.

To compute the 3-year ahead errors, a single forecast is used: the Final2007 forecast for 2010. This forecast is represented by the square shaped symbol on the 2007 forecast line.

In all cases, the error is computed from the difference between the symbols on each forecast line and the corresponding weather normalized actual value. The residuals are computed as Predicted-Actual, so a positive value indicates an overprediction.

The Year ahead statistics are compared in Figure 5, which shows the mean absolute error statistics for all three methods. As shown, Index 2 has a slight accuracy edge for the 1-Year ahead forecasts, but Index1 performs better in the 2-Year ahead and 3-Year ahead time frames.

Figure 5: Comparison of Accuracy Statistics

Years Ahead	GMP	Index1	Index2
1-Year Ahead 	2.64%	2.52%	2.51%
2-Year Ahead 	5.87%	5.19%	5.26%
3-Year Ahead 	6.66%	5.50%	5.67%

These statistics are repeated for each of the zones for the 1-Year statistics in Figure 6, for the 2-Year statistics in Figure 7, and for the 3-Year Statistics in Figure 8. These figures show coincident peak (CP) statistics on the left and non coincident zone peaks (NCP) on the right. In these figures, the cell highlighted in Green on each row has the best accuracy of the three methods for the zone and forecast time frame.

The conclusions are the same whether the CP or NCP statistics are used.

- For the 1-Year statistics, Index2 has a slight edge over the other methods, based on the average of the zone statistics. It has the best accuracy for 9 of the 18 zones for CP and 11 of the 18 zones for NCP.
- For the 2-Year statistics, Index1 and Index2 are comparable. Index1 has the best accuracy for 8 of 18 zones for both CP and NCP. Index2 has the best accuracy for 8 of 18 zones for both CP and 7 of 18 zones for NCP. The GMP method has the best accuracy for only 2 zones (Penelec and Dayton).
- For the 3-Year statistics, Index1 and Index2 are both about 1% more accurate than the GMP method. Index1 has a slight edge, and has the best accuracy for 10 of 18 cases for CP and 8 of 18 cases for NCP.

Forecast Stability.

Forecast stability is a concern for many forecasting methods. The stability of a forecast reflects the stability of the underlying variables. These variables are subject to changes, and these changes can result from economic data as well as from changes in growth rates.

To measure stability, two points about 5 years from the target year are computed by taking the average of the values for each target year. These represent a method standard.

This idea is depicted in Figure 9. The statistics are the Average value of the recast values and the Coefficient of Variation (average).

Figure 9: Depiction of Stability Statistics – PJM Peaks, GMP Method

Stability results are summarized in Figures 10 and 11 for the CP results by zone. Figures 12 and 13 summarize the NCP results.

At the RTO level, the Index methods (CV values of 2.10% and 2.07%) show slightly less variation at the 5-year level than the GMP method, with a CV of 2.18%. At the 10-year level, this difference becomes more pronounced, with CV values of 2.89% for GMP versus 2.40% (Index1) and 2.46% (Index2) for the Index methods.

The stability advantage of the Index methods is more pronounced at the zone level. Focusing on the NCP statistics in Figures 12 and 13:

- The Index methods have better stability statistics (smaller CV values) in 16 of the 18 cases at the 5-year horizon and in 15 of the 18 cases at the 10-year horizon.
- At the 5-year horizon, the average CV value across zones is slightly lower for Index2 (2.16%) than it is for Index1 (2.21%). Both are more stable than the GMP method, which has an average CV value of 2.86%.
- At the 10-year horizon, the average CV value across zones remains slightly lower for Index2 (2.77%) than it is for Index1 (2.79%). Both are significantly more stable than the GMP method, which has an average CV value of 4.17%.

Conclusions Related to Accuracy and Stability

In the Phase I report, Recommendation #1 was to implement the Index1 approach. This approach combines economic variables using a set of weights based on the industry survey. This recommendation was based on the following logic:

- On a conceptual level, the index approaches are preferred to a method with a single driver such as GMP. The underlying economic theory and end-use modeling frameworks suggest different drivers for different customer segments. As indicated by the industry survey, utility modelers typically drive their sales and peak models with corresponding sector-oriented variables.
- In the three test cases that were examined, the Index-based forecasts were more consistent with historical peak growth rates.
- Reflecting the results of the industry survey, we concluded that the index approaches will provide zone forecasts that are more consistent with forecasts developed by the utilities.
- In the three test cases, the two index approaches had about the same historical fit. The simpler approach (Index1) actually performed slightly better in all three cases than the sector -weighted approach (Index2).

Following this recommendation there was significant discussion about the need to test the forecast accuracy of the Index methods relative to the GMP method. In these discussions Itron stressed the need to use true forecast test statistics, rather than statistics based on withheld sample points or backcasts where the true X variable values are known. Based on our observations about the GMP data and forecasts for the three test regions that were examined, we expected that use of an Index approach would provide better forecast accuracy and reduced forecast volatility.

The analysis presented above confirms these expectations. The index methods are consistently more accurate and give more stable forecasts than the GMP based method. The results do not indicate a strong advantage for one index approach over the other. Index1 appears to have a slight edge in terms of accuracy at the PJM level. Index2 appears to have a slight advantage in terms of stability.
